Adolescent adjustment in at-risk families: The role of psychosocial stress and parental socialization

Bárbara Lorence Lara, 1 Ma. Victoria Hidalgo García, 2 Maja Dekovic 3

SUMMARY

Introduction
The study of factors associated with internalizing and externalizing problems in adolescents living in at-risk families is a subject of recent interest in mental health in Spain. The presence of mental health problems in children and adolescents is too frequent in these families due to their high exposure to a variety of risk factors and the lack of protection factors. However, few studies have examined the contribution of specific factors to each type of mental health problem in adolescents from at-risk Spanish families. This study strives to contribute to knowledge in this field, by analyzing the role of two important dimensions frequently linked to adolescents’ adjustment: psychosocial stress and parental socialization. Likewise, this study seeks to identify whether both dimensions predict differently for two types of mental health problems in adolescents from at-risk families.

Methodology
The sample was composed by 134 Spanish adolescents (56 girls and 78 boys) with an average age of 13.52 (SD = 1.57). These adolescents grew up in families who were receiving psychosocial intervention from Social Services in Spain for family preservation reasons. This research is considered to be a cross-sectional descriptive study and the instruments administered allowed the collection of data about mental health problems, psychosocial stress, parental socialization and intervention data by Social Services.

Results
The hierarchical multiple regression models showed that both dimensions (psychosocial stress and parental socialization) were significantly related to mental health problems, but a different pattern of findings emerged for each type of problem. When co-morbidity between both problems was controlled, psychosocial stress was mainly related to internalizing problems, whereas parental socialization predicted the externalizing ones.

Discussion and conclusions
This study underscores the importance of distinguishing between two types of mental health problems analyzed (internalizing and externalizing) and emphasizes that both, the enhancement in parental socialization as well as the training of adolescents in positive social skills to cope better with stressful life events, should be part of at-risk family programs.

Key words: Risk, family research, adolescent, mental health, Psychological stress, parental socialization.

RESUMEN

Introducción
El estudio de factores asociados con problemas internalizantes y externalizantes en adolescentes que viven en familias en riesgo es objeto de interés reciente en salud mental en España. La presencia de problemas de salud mental en menores y adolescentes es demasiado frecuente en estas familias debido a la alta y variada exposición a factores de riesgo, así como a la falta de elementos de protección que les rodean. Sin embargo, pocos estudios han examinado la contribución que factores específicos hacen a cada tipo de problemas de salud mental en adolescentes de familias españolas en riesgo. Este estudio intenta contribuir al conocimiento en este campo, analizando el papel de dos dimensiones frecuentemente relacionadas con el ajuste adolescente: estrés psicosocial y socialización parental. Asimismo, este estudio trata de identificar si ambas dimensiones predicen de forma diferente los dos tipos (internalizantes y externalizantes) de problemas de salud mental en adolescentes de familias en situación de riesgo.

Metodología
La muestra se compone de 134 adolescentes españoles (56 chicas y 78 chicos) con una media de edad de 13.52 (DT=1.57). Estos adolescentes crecieron en familias que estaban recibiendo una intervención psicosocial por parte de los Servicios Sociales españoles por razones de preservación familiar. El diseño de esta investigación es de carácter transversal y descriptivo. Los instrumentos administrados permitieron recabar datos sobre problemas de salud mental, estrés psicosocial, socialización parental y la intervención recibida por los Servicios Sociales.

Resultados
Los modelos de regresión múltiple jerárquica mostraron que ambos dominios (estrés psicosocial y socialización parental) estuvieron significativamente relacionados con los problemas de salud mental, pero emergió un patrón de resultados diferentes para cada tipo de problemas. Cuando la comorbilidad entre ambos problemas fue controlada, el estrés psicosocial estuvo significativamente relacionado con los
Multiple features of the adolescents’ environment, such as quality of parenting and the psychosocial stress experienced, have been directly linked to adolescents’ risk for maladjustment (e.g.). However, there are no conclusive data for adolescents growing up in at-risk families, because few studies have carefully analyzed the role of parental socialization and psychosocial stress in adolescent development in this type of family. Undoubtedly, the label “at-risk families” can cover a wide variety of family situations. Given the complexity of the processes that lead to family psychosocial risk, the authors concur with Rodrigo et al. in defining these families as: “those in which the persons responsible for the care and education of the minor, due to personal and relational circumstances, are neglectful of their parental functions or use them inappropriately, compromising or prejudicing the minor’s personal and social development, but without the situation attaining a degree of severity that would justify a foster care order whereby it were considered appropriate to separate the minor from his or her family”.

Current risk and protection models recognize family functioning as complex and multilevel. Research has considered specific family characteristics as risk factors for adolescent development: for example, the importance of economic pressure, truancy, dysfunctional marital relations, complicated life trajectories, psychosocial stress and conflictive parents-children interactions (e.g.). In some theoretical models, psychosocial stress (related to cumulative stressful life events) is considered an important concept to explain the maladjustment. It is emphasized that risk factors have a tendency to reinforce one another. In other words, the risk factors tend to multiply and amplify their impact as the factors accumulate. As the occurrence of risks increases, accompanying stress might weaken the person’s coping strategies.

Psychosocial stress has often been studied in at-risk families, especially when the topic of the study is adolescent adjustment. During adolescence, boys and girls in general are more vulnerable to psychosocial stress, but this might be especially true for teenagers living in adverse family circumstances. These adolescents are exposed to a variety of stressful life events, and the lack of resources available in these contexts tends to increase risk for their adjustment. Thus, several studies have found data that show a strong association between accumulation of stressful events in adolescents and internalizing and externalizing problems, in both non-at-risk families and at-risk families.

The existence of stressful events in children’s lives is very important for adjustment problems. Nevertheless, some boys and girls in even the most adverse negative circumstances develop normally, or may even function at a high level. Child and adolescent well-being is expressed by the complex and multivariate function process emerging from the transaction of intrapersonal and interpersonal factors over time in specific familiar and extra-familiar contexts. There are many factors that act as protective elements from the negative effects caused by stressful circumstances. There is an extensive research tradition exploring how parental socialization constitutes an important protective factor for adolescent development. The influence of parenting practices seems to be particularly relevant during times of stress.

Parental socialization has historically been one of the most popular topics in the field of developmental psychology, mainly because of its association with developmental outcomes for children and adolescents (e.g.). Many professionals have expressed a special interest in the study of this dimension during adolescence. This is mainly due to four important reasons: 1) adolescence is a period when many changes take place in the lives of children and their families, thus making children more vulnerable to more stressful psychosocial experiences. 2) It is a period when conflicts between parents and adolescents increase. At this stage, adolescents have to renegotiate their position within the family and this is often the main cause of increased family conflicts. 3) During this period, parents tend to change their parental socialization practices. This change is linked to new needs and interests of boys and girls during this stage, and to parents’ own developmental processes. 4) Despite the existence of other, extremely influential development contexts, such as peers, adolescent adjustment is still related to parenting behavior.

The relevance of parental socialization during adolescence can be analyzed from two perspectives: 1) focusing on categorical parenting styles, or 2) focusing on the traditional parenting dimensions: Acceptance/Involvement (responsiveness, inductive strategies) and Strictness/Imposition (harsh parenting). According to Cumming et al., the distinct nature of these two dimensions advanced the understanding of the influence of specific parental practices on child adjustment. For this reason, this study has been carried out within the second
framework, analyzing parenting dimensions separately. 

According to the dimensional perspective, several studies have shown that adolescents who perceive their parents as affectionate, caring and communicative (Acceptance/Involvement) have fewer indicators of internalizing and externalizing problems (e.g.). Various arguments have been given to explain the positive effect of these practices on adjustment in adolescence, which highlight that this pattern of parental behavior creates a favorable family environment that makes adolescents more sensitive and responsive to the influence of family. In the absence of such environment, adolescents are more likely to disregard advice and rules established by parents.

There is no consistent data on whether Acceptance/Involvement practices are more beneficial for externalizing problems than for internalizing ones. Some studies have found that responsiveness behaviors play a more important role in internalizing than externalizing problems, but others show that relations between supportive aspects of parenting appear to be stronger for externalizing than for internalizing problems.

The association between problem behavior and Strictness/Imposition is even less clear. This dimension has been measured in different ways; depending on the measures used, the studies have shown different results. The instrument used in this study understands Strictness/Imposition as harsh parenting, including parental practices such as verbal scolding, physical punishment and revoking privileges. Empirical studies have shown that parents who use harsh parenting are linked with high levels of both externalizing problems and internalizing problems. In some studies, the relationship with internalizing problems has been found only in the presence of high levels of harsh parenting.

Exposure to Strictness/Imposition during adolescence is thought to increase children’s risk for adjustment problems during the adolescence period for two reasons: Patterson’s theory of coercive family process suggested that negative exchange within the parent-adolescent relationship eventually leads to the teaching, socialization, and acquisition of antisocial and aggressive behaviors. Conversely, those parents who are able to maintain positive relations with their adolescent children facilitate pro-social development, and thus have the potential to reduce, within the peer group, the likelihood of maladaptive behaviors (such as violent aggression). Coercive techniques have also been associated with increases in feelings of humiliation and helplessness.

Although several studies have indicated the importance of these two parenting dimension for adolescent adjustment, some results revealed that the dimensions can have different meanings depending on the socio-cultural environment analyzed. From these data, it could be argued that there is no single type of parenting that is suitable for all adolescents and in every family context. Therefore, it is necessary to explore specific relationships between parental socialization and problem behavior in different families, such as at-risk families in Spain. There are still several fields that need in-depth study of those adolescents who grow up in these families. According to the available data, at-risk families are characterized by inadequate parenting practices. Usually, these families use harsh and punitive parental practices in the relationships with their children. Some authors argue that this type of parental behavior pattern is due to family distress suffered by parents in these contexts.

There has been speculation that strict parenting practices are adaptive and beneficial for adolescent wellbeing in specific social contexts; for example, those characterized by unsafe or dangerous neighborhoods. In an at-risk context, parenting practices based on strictness and coercion could guarantee the safety of the children and adolescents. On this assumption, some studies have shown that low levels of autonomy granting, high parental restriction and punitive parenting are beneficial practices for adolescents living in high-risk communities, when compared with those growing up in low-risk communities, especially concerning the externalization of problems (e.g.). According to Belsky, Steinberg and Draper, differences between these groups may reflect specific adaptive solutions of the parents to problems posed by the characteristic demands of a particular environment.

In summary, a theoretical review indicates that authors have assumed an association between parental socialization and psychosocial stress on problem behavior in community families. Few empirical studies, however, have statistically tested these assumptions with at-risk families. To fill this lack of studies, the present study seeks to analyze these associations in at-risk families, by controlling the co-morbidity between internalizing and externalizing problems. Interestingly, both problem behaviors tend to co-occur in such a way that children who are rated high on internalizing problems also tend to be rated high on externalizing problems (e.g.). Accordingly, the comparison of the prediction results in controlling or not co-morbidity between mental health problems could be different. Thus, when both behavior problems are analyzed as separate dependent variables, without controlling for the co-variation between the score, there is a risk of repeatedly predicting the common variance rather than independently predicting variance that is unique to each problem domain.

The present study attempts to expand the existing knowledge of the prediction of parental socialization and psychosocial stress in a specific environment: at-risk family contexts that have received psychosocial intervention from Social and Community Services for family preservation, during adolescence. The main aim of this study is to examine the unique effects of psychosocial stress and parental socialization on behavior problem in these adolescents. Moreover, the work examines whether the predictors of problem in this at-risk sample differ for two types of prob-
lem behaviors, internalizing and externalizing problems, when co-morbidity between both is controlled or not.

First, based on previous studies, the authors consider both domains —parental socialization and psychosocial stress— to be relevant predictors for adolescent problem behavior in families at-risk. Second, the study hypothesized that the Acceptance/Involvement dimension would predict both types of problem behaviors, whereas harsh parenting, in the present study defined as Strictness/Imposition, would be more important for externalizing than for internalizing problems. Finally, the authors expected that the relations between parental socialization and psychosocial stress, on the one hand, and problem behavior, on the other, would be different if co-morbidity between the two types of problem behavior is controlled.

**METHOD**

**Participants**

The sample consisted of 134 adolescents, 56 girls (41.8%) and 78 boys (58.2%) from Seville (Spain), ranging in age from eleven to seventeen ($M=13.52$, $SD=1.57$). These adolescents lived in families who were receiving psychosocial intervention from Sevilla City Social Services in Spain, for family preservation reasons. Family preservation includes all those steps that must be taken to keep a child within his/her family when those responsible for the child’s care, health and education, for various reasons, have abandoned their parental roles or make inappropriate use thereof, compromising or damaging the child’s social and personal development, but without reaching a point to justify his/her separation from the family. The adolescent in this study were experiencing a family situation that required the support of Social Services, and actively participated in any of the specific programs for families at risk carried out by Social Services. Specifically, 47.8% of the parents of these families were participating in a preventive parent education program and 51.7% of the adolescents were participating in social education programs.

A high percentage of these families were single-parent families (44.7%) and the parents were characterized by low-skilled jobs (86.2%), uncertain employment (41.5%) and a low educational level (45.5% elementary education not completed). The families lived in small houses ($M=69.50$ m$^2$, $SD=13.35$ m$^2$) and the mean number of children per family was $2.46$ ($SD=1.07$).

**Procedure**

Professionals (psychologists and social workers) from the eleven Social Services districts of the Seville City Hall selected 134 adolescents for this study, based on the following criteria: 1) the family had been referred by Social Services as living in at-risk psychosocial conditions, and 2) some member of the family had received preventive psychosocial intervention from this Social Protection System.

This research is considered as a cross-sectional descriptive study. The instruments were administered at adolescents’ homes or in the classroom where the education program was offered. Adolescents completed a battery of questionnaires in Spanish for 90 minutes. Researchers stayed in the room during this task and then conducted the interview. The evaluation consisted of two parts: first, the adolescents filled out three self-report instruments, and the second part consisted of a personal interview to complete the questionnaire on parental socialization. Parents’ data were collected directly from psychologists employed by Social Services.

**Measures**

**Behavioral problems.** Participants completed the Youth Self-Report (YSR). This questionnaire consisted of 112 items that measured eight mental health subscales: withdrawn (e.g., "I would rather be alone than with others"), somatic complaints (e.g., "I feel dizzy or lightheaded"), anxiety and depression (e.g., "I cry a lot"), social problems (e.g., "I’m too dependent on adults"), thought problems (e.g., "I see things that other people think aren’t there"), attention problems (e.g., "I feel confused or in a fog"), aggressive behavior (e.g., "I destroy things belonging to others"), and rule-breaking behaviors (e.g., "I steal from places other than home"). The first three subscales, composed of 21 items, were referred to as "internalizing problems", while the last two were referred to as "externalizing problems" and included 32 items. Adolescents selected a response from 0 (not true) to 2 (very true). Cronbach’s alphas for this study were $\alpha = .79$ for internalizing problems and $\alpha = .86$ for externalizing problems.

**Psychosocial stress.** This variable was evaluated by means of a self-report measure designed by Oliva, Jiménez & Parra consisting of a list of 29 negative events likely to be experienced by adolescents in the family (e.g., "parental divorce"), school (e.g., "important problems with teachers"), peer contexts (e.g., "breaking up with boy/girlfriend") and personal event (e.g., "pregnancy"). Each item was scored "1" if the specific event had occurred and "0" if the event had not occurred in the last five years. When adolescents answered that an event had occurred, they were asked to rate the emotional impact that this event had on their lives from 1 (none) to 10 (very high). A total score of Stressful Life Events was achieved by adding up all negative events experienced. A second score, Emotional Impact, was obtained by the sum of the emotional impact data divided by the sum of stressful life events. The reliability analysis of this sample showed $\alpha = .72$ for Stressful Life Events and $\alpha = .81$ for Emotional Impact.

**Parental socialization.** Participants were interviewed to complete the "Parental Socialization Scale for Adolescents"
In this instrument, the adolescent was asked to assess the socialization styles of both parents in 29 situations representative of everyday family life: thirteen compliance situations (e.g., “a teacher calls mother and tells her that you are behaving well in class”) and sixteen non-compliance situations (e.g., “you arrive home late”), to assess parental practices from 1=never to 4=always. In each of the thirteen compliance situations, the adolescent had to rate the parenting practices of Affection (“my mother shows affection”) and Indifference (“my mother seems indifferent”). In each of the sixteen non-compliance situations, offspring, the adolescent had to rate the parenting practices on Dialogue (“my mother talks to me”), Detachment (“my mother doesn’t tell me anything”), Verbal Scolding (“my mother scolds me”), Physical Punishment (“my mother spanks me”) and Revoking Privileges (“my mother takes something away from me”). This questionnaire consisted of 116 items for each parent and allowed the study to obtain two dimensions of parenting: 1) the Acceptance/Involvement dimension was obtained by averaging the responses on Affection, Dialogue, Indifference, and Detachment (the last two subscales were reversed code); 2) the Strictness/Imposition dimension was calculated by averaging the responses on Verbal Scolding, Physical Punishment, and Revoking Privileges.

This scale was originally validated in Spain with a sample of almost 3000 adolescents between the ages of ten and eighteen and the questionnaire was recently used in different studies. The reliability analysis showed α=.96 for the Acceptance/Involvement and α=.92 for the Strictness/Imposition.

Intervention by social services. Social Services professionals provided information about the type of intervention each family obtained. The types of intervention were: Level 1: voluntary education program, without specific intervention by Social Services, 23.9% of participants; Level 2: economic and informative support from Social Services, 20.1% of participants; Level 3: specific family intervention by Social Services to promote their social reintegration, 48.5% of participants; Level 4: an intervention by Social Services because of a threat to the integrity of the children who lived in this context, 7.5% of participants.

**RESULTS**

### Descriptive statistics and bivariate associations

Table 1 shows the means, standard deviations, and bivariate correlations among adolescent mental health problems, psychosocial stress and parental socialization (Acceptance/Involvement and Strictness/Imposition).

*p < .05; **p < .01; ***p < .001.
Inter-correlation between both adolescent behavioral problem domains was significant, indicating that externalizing problems were positively associated with internalizing problems. Regarding the relationships between psychosocial stress and behavioral problems, two correlations were significant. A higher level of stressful life events was linked with a higher level of externalizing problems, while a higher level of emotional impact was associated with a higher level of internalizing problems. Bivariate correlations between parenting behavior dimensions and adolescent outcomes indicated that acceptance/involvement and strictness/imposition were negatively associated with externalizing problems, but not with internalizing problems. Dimensions of socialization practices were positively interrelated, but both dimensions were unrelated to psychosocial stress measures.

**Predicting adolescent adjustment in at-risk families**

The results of hierarchical multiple regression models are presented in table 2. First, the effects of parenting behaviors and psychosocial stress on adolescent adjustment were examined, without controlling the co-varying adjustment problems domain (Model 1). The results indicate that the internalizing problems domain explained 14% of the variance, whereas the percentage of the variance for the externalizing problems domain was 11%.

For internalizing problems, psychological stress accounted for 7% of the variance after being controlled for sex, age and familiar intervention by Social Services. In addition, parental socialization additionally predicted 5% of the variance of this variable. Specifically, emotional impact and parental acceptance were significant predictor variables of internalizing problems. Regarding externalizing problems, the analyses indicated that parental socialization explained 12% of the variance with only parental acceptance being the unique significant predictor.

In the second set of analyses (Model 2), the effect of co-varying problem behavior type was controlled to analyze the specificity of the relationship between psychosocial stress and the parenting dimensions, on the one hand, and each type of behavioral problem, on the other. Models showed that internalizing problems explained 18% of total variance and externalizing problems explained 15% of total variance. When co-occurring psychopathology was included in these models, psychosocial stress and parental socialization explained less of the variance in adolescent outcomes than previously, both for mental health problems. In this analysis, both dimensions (psychosocial stress and parental socialization) explained 9% of internalizing problems and 12% of externalizing problems compared with 12% and 15%, respectively, in previous models.

These results confirmed the importance of emotional impact as a significant predictor of internalizing problems. However, parental acceptance ceased to be significant once the co-morbidity was controlled. This suggests a possible lack of unique effects of the parental acceptance on the internalizing problems. For externalizing problems, there was a difference between the first and second model. After controlling for the internalizing problem dimension, both the strictness/imposition and acceptance/involvement dimensions proved to be significant predictors of the externalizing problems. These data showed the specificity of the relation between parental socialization and externalizing problems.

**DISCUSSION**

The findings of this research were relevant in several ways. First, this study examined the unique effect of parental social-
Adolescent adjustment in at-risk families

Vol. 36, No. 1, enero-febrero 2013

The results found in this research supported this finding when externalizing problems were not controlled, but this association disappeared when this co-varying psychopathology was controlled. According to Callahan et al., this result emphasizes the importance of analyzing the unique effects in this field. Similar findings have been reported by Parra and Oliva, who found a weaker association between this parenting dimension and internalizing problems compared with externalizing ones. According to these authors, it is also necessary to consider the influence of other socialization contexts, such as peers, and biological variables on internal maladjustment.

Regarding the Strictness/Imposition dimension, our findings showed that externalizing problems were negatively predicted by harsh and coercive parental practices in the adolescent sample growing up in at-risk contexts. This study supports previous findings in other studies with at-risk samples: adolescents in at-risk families are exposed to a high occurrence of risk events and this exposure increases the risk for maladjustment. Probably, a high level of strict control and firm limit setting in these families contribute to a decrease in behavioral problems such as aggression, addiction, etc. According to Belsky et al., differences between at-risk samples and community samples reflect specific adaptive solutions to problems characteristic of a particular context. The findings from this study showed that parenting characterized by strictness and imposition was not as negative for adolescent adjustment in at-risk families as other studies have found in community family contexts. One must remember, however, that this finding does not mean that a extreme level of strict control is favorable for at-risk adolescent adjustment, because, although this sample could be characterized as an at-risk sample, the parents still show relatively low level of strictness. In other words, this is not a sample of maltreatment families, who use strict control daily. One should be careful in generalizing these results for a larger or different population.

Finally, the third aim was to examine if there are different predictors of internalizing and externalizing problems during adolescence. The findings indicate that psychosocial stress is more important for internalizing problems, whereas parental socialization is more important for externalizing problems. These differences in the role of parental socialization on behavior problems may be explained by the fact that internalizing problems refer to the private dimension influenced by multilevel interactive factors (biological and social) during adolescence. It is also possible that parents do not recognize their adolescents’ internalizing problems and fail to react to them, which contrasts with externalizing problems that are more visible and tend to elicit a reaction from the parent. On the other hand, it is also possible that other aspects of socialization, such as the parent’s own well-being, might be more important for adolescents’ internalizing problems than the parenting dimension assessed in the present study. For example, there is strong scientific evidence that maternal depression is associated with adolescent internalizing problems, suggesting that maternal well-being may play an important role in child internalizing symptoms.

In conclusion, this research indicates the importance of parental socialization for externalizing problems of adolescents in at-risk contexts and psychosocial stress for internalizing problems. Previous studies have shown a high prevalence of externalizing and internalizing problems in boys and girls growing up in at-risk families. This study suggests that prevention and/or intervention efforts to help these adolescents should include two components: first, working with parents to enhance their supportive and controlling socialization practices, and second, training adolescents in problem-solving strategies, to adequately address the high number of stressful events they have to confront daily.

Several limitations of this research should be noted. First, data were obtained exclusively from adolescents as the
sole source of information. Second, the findings of this study were based on an at-risk sample of adolescents, but at-risk diversity was found in this sample. Third, because of the cross-sectional nature of these data, the authors cannot conclude that parental socialization is actually a cause of externalizing problems in at-risk samples of adolescents. Future research should include data from multiple sources (parents or teachers), increase the sample size to analyze differences by family risk levels and, finally, obtain data from different moments of the adolescent’s life (longitudinal studies).

ACKNOWLEDGMENTS

Funds for this study were provided by Seville Council, the Ministry of Education and Science (SEJ2007-66105) and Regional Ministry of Economy, Innovation and Science, Regional Government of Andalusia (Research fellowship FPDI).
